Parsing Tweets into Universal Dependencies

Anonymous ACL submission

Abstract

We study the problem of analyzing tweets with universal dependencies (UD; **?**). We extend the UD guidelines to cover special constructions in tweets. Using the extended guidelines [including tokenization, POS tagging and parsing? (need to mention the annotation process/pipeline system not only consists parsing in abstract) —YI], we create a new tweet treebank (TWEEBANK V2), which has 55,607 tokens with labeled attachments. It is more than four times larger than the (unlabeled) TWEEBANK V1 introduced by **?**. We characterize the disagreements among our annotation and show that it is challenging to deliver consistent annotation due to ambiguity in understanding and explaining tweets. Using the new treebank, we build a pipeline system to parse raw tweets into UD. To overcome the annotation noise without sacrificing computational efficiency, we propose a new method to distill an ensemble of 20 transition-based parsers into a single one. Our parser achieves an improvement of 2.6 in LAS over [which comparison is this? —NAS][$^{\text{Y}}_{\text{L}}$my bad, it was fixed.] the baseline and outperforms parsers that are state-of-the-art on other treebanks in both accuracy and speed.

1 Introduction

NLP for social media messages [texts? —YI] is challenging, both [not only —YI] because domain adaptation is required, but also because [delete 'because' ? —YI] creating annotated datasets (e.g., treebanks) for training and evaluation is hard. Pioneering work by **?** annotated 7,630 tokens' worth of tweets according to the phrase-structure conventions of the Penn Treebank (**?**, PTB). Stanford dependencies were converted afterwards in their work [by who? —NAS][$^{\text{Y}}_{\text{L}}$by themselves]. **?** further studied the challenges in annotating tweets and presented a tweet treebank (TWEEBANK), consisting of 12,149 tokens and largely following conventions suggested by **?**, fairly close to **?** dependencies (without labels). Both annotation efforts were highly influenced by the PTB, whose guidelines have good grammatical coverage on newswire. However, when it comes to informal, unedited, user-generated text, the guidelines may leave many annotation decisions unspecified.

Universal dependencies (**?**, UD) were introduced to enable consistent annotation across different languages. To allow such consistency, UD was designed to be adaptable to different genres (**?**) and languages (**??**). We propose [believe? —YI] that analyzing the syntax of tweets can benefit from such adaptability. In this paper, we introduce a new tweet treebank of 55,607 tokens that follows the UD guidelines, but also contends with social media-specific challenges that were not covered by UD guidelines. Our annotation includes tokenization, part-of-speech (POS) tags, and (labeled) [no need for parenthesis —YI] universal dependencies. We characterize the disagreement among our annotations [annotation(s) and disagreement(s). check abstract, same sentence, different singularity/plurality. I think should be 'disagreement' and 'annotations' —YI] and find that consistent annotation [again, it needs to be the same all the time at least for me. —YI] is still challenging to deliver even with the extended guidelines.

Based on these annotations, we designed a pipeline to parse raw tweets into universal dependencies. Our pipeline includes: a bidirectional

LSTM (bi-LSTM)[need cite lstm/bi-lstm here? —YI] tokenizer, a word cluster-enhanced POS tagger (following **?**) [no need for parenthesis? —YI], and a stack LSTM parser with character-based word representations (**?**), which we refer to as our "baseline" parser. To overcome the noise in our annotated data and achieve better performance without sacrificing computational efficiency, we distill a 20-parser ensemble into a single greedy parser (**?**). We show further that learning directly from the exploration of the ensemble parser is more beneficial than learning from the gold standard "oracle" transition sequence. Experimental results show that an improvement of more than 2.6 points [again, not sure what this is quoting —NAS][$^{Y}_{L}$fixed] in LAS over the baseline parser can be achieved with our distillation method and that [delete 'that'? —YI] it outperforms other state-of-the-art parsers in both accuracy and running speed.

The contributions of this paper include:

- We study the challenges of annotating tweets in UD (§2) and created a new tweet treebank (TWEEBANK V2), which includes tokenization, part-of-speech [POS —YI] tagging, and labeled universal dependencies annotation. We also characterize the difficulties of creating such annotation.
- We introduce and evaluate a [pipeline —YI] system to parse the raw tweet text into universal dependencies (§3). Experimental results show it performs better than a stack of the state-of-the-art alternatives. [say it performs better than existing systems? —NAS][$^{Y}_{L}$added.]
- We propose a new distillation method for training a greedy parser, leading to better performance than existing methods and without efficiency sacrifices.

We release our dataset and our [delete 'our' —YI] system as open-source software [delete 'as open-source software'? —YI] at `http://anonymized`.

2 Annotation

We first review TWEEBANK V1 of **?**, which is [was —YI] the largest [unlabelled —YI] Twitter dependencies annotation (§2.1). Then we introduce the differences in our tokenization (§2.2) and part-of-speech (§2.3) (re)annotation with **?** and **?**, respectively, on which TWEEBANK V1 was built. We describe our effort of adapting the UD conventions to cover tweet-specific constructions (§2.4). Finally, we present our process of creating a new tweet treebank, TWEEBANK V2, and characterize the difficulties in reaching consistent annotations (§2.5).

2.1 Background: TWEEBANK

The annotation effort we describe stands in contrast to [the? —YI] previous work by **?**. Their aim was the rapid development of a dependency parser for tweets, and to that end they contributed a new annotated corpus, TWEEBANK, consisting of 929 tweets. Their annotations added [unlabelled —YI] dependencies to a portion of the data annotated with POS tags by **?** and **?** after rule-based tokenization (**?**). Kong et al. also contributed a system for parsing; we defer the discussion of their parser to §3.

Kong et al.'s rapid, small-scale annotation effort was heavily constrained. It was carried out mostly by nonnative speakers [should not emphasize non-native speakers (v2 also built by non-native speakers), but emphasize annotators with only cursory training, no clear annotation guidelines, no consensus/agreement on controversial cases, allow annotators to underspecify part of the tree and allow multiple different trees for the same tweets —YI], in a very short amount of time (a day). Driven both by the style of the text they sought to annotate and by exigency, some of their annotation conventions included:

- Allowing an annotator to exclude tokens from the dependency tree. A clear criterion for exclusion was not given, but many tokens were excluded because they were deemed "non-syntactic"[(e.g. retweet sign, topical hashtags, ...) —YI].
- Allowing an annotator to merge a multiword expression into a single node in the dependency tree, with no internal structure. Annotators were allowed to take the same step with noun phrases.
- Allowing multiple roots, since a single tweet might contain more than one sentence.

These conventions were justified on the grounds of making the annotation easier for non-experts, but they must be revisited in our effort to apply UD to tweets.

2.2 Tokenization

Our tokenization strategy lies between the strategy of **?** and that of UD. There is a significant [significant? not really —YI] tradeoff between preservation of original tweet content and respecting the UD guidelines.

The regex-based tokenizer of **?**—which was originally designed for an exploratory search interface called TweetMotif, not for NLP—preserves most whitespace-delimited tokens, including hashtags, at-mentions, emoticons, and unicode glyphs. They also treat contractions and acronyms as whole tokens and do not split them. UD tokenization,[1] in order to better serve dependency annotation, treats each syntactic word as a token. They therefore more aggressively split clitics from contractions (e.g., *gonna* is tokenized as *gon* and *na*; *its* is tokenized as *it* and *s* when *s* is a copula)[I think the examples are not contractions (can't), is there a name for such words? —YI]. But acronyms are not touched in the UD tokenization guidelines. Thus, we follow the UD tokenization for contractions and left acronyms like *idc* as a single token. [unless we make a change, I think we need to say here that acronyms like *idc* are left as a single token —NAS] [$^{Y}_{L}$ mentioned acronymns, we don't have the problem of normalization, cause normalization was just annotated for data study.]

In the different direction of splitting tokens, UD guidelines also suggest to merge [suggest merging? —YI] *multi-token words* (e.g. *20 000*) into one single token in some special cases. We witnessed a small number of tweets that contain multi-token words (e.g. *Y O*, and *R E T W E E T*) but didn't combine them due to simplification. Such tokens only account for 0.067% and we use the UD *goeswith* relation to resolve these cases in the dependency annotations.

2.3 Part-of-Speech Annotation

Before turning to UD [dependencies —YI] annotations, we (re)annotated the data with POS [tags —YI], for consistency with other UD efforts, which adopt the universal POS tagset of **?**. In some cases, conflicts arose between the UD English treebank conventions (**?**, UD_English)[2] and the conventions of **?** and **?**. [The conflicts should refer to a **noncorresponding tag** from that of gimpel to UDEnglish, cuz they dont have the same tagset. —YI] In these cases, we always conformed to UD, enabling consistency (e.g., when we exploit the existing UD_English treebank in our parser for tweets, §3). For example, the nominal URL in Figure 2 is tagged as *other* (X) and + is tagged as *symbol* (SYM) rather than *conjunction* (CCONJ).

Tokens that do not have a syntactic function (discussed at greater length in the next section) were usually annotated as *other* (X), except for emoticons, which are tagged as *symbol* (SYM), following UD_English.

Tokens that abbreviate multiple words, such as *idc* ("I don't care") are resolved to the POS of the syntactic head of the expression, following UD conventions (in this example, the head *care* is a verb, so *idc* is tagged as a verb). When the token is not phrasal, we use the POS of the left-most sub-phrase. For example, *mfw* ("my face when") is tagged as a noun (for *face*).

Compared to the coarse-grained [fine-grained? —YI]POS tagging effort of **?**, our approach simplifies some matters. For example, if a token is not considered syntactic by UD conventions, it gets an *other* (X) tag (Gimpel et al. had more extensive conventions). Other phenomena, like abbreviations, are more complicated for us, as discussed above; Gimpel et al. used a single part of speech for such expressions.

Another important difference follows from the difference in tokenization. As discussed in §2.2, UD calls for more aggressive tokenization than that used by **?** [YICOMMENT: should be OCONNOR's paper? TOKENIZATION? —YI]. In particular, Gimpel et al. [SAME HERE —YI] opted out of tokenizing contractions and possessives, introducing new parts of speech instead.[3] For us, these tokens must be split, but universal parts of speech can be applied.

2.4 Universal Dependencies Applied to Tweets

We adopt UD version 2 guidelines to annotate the syntax of tweets. In applying UD annotation conventions to tweets, the choices of **?** must be revisited. We consider the key questions that arose in our annotation effort, and how we resolved them.

[1] http://universaldependencies.org/u/overview/tokenization.html

[2] https://github.com/UniversalDependencies/UD_English

[3] These tags only account for 2.7% of tokens, leading to concerns about data sparseness in tagging and all downstream analyses.

	syntactic (%)	non-syntactic (%)
emoticons	0.25	0.95
RT	0.14	2.49
hashtag	1.02	1.24
URL	0.67	2.38
truncated words	0.00	0.49
total	2.08	7.55

Table 1: Proportions of non-syntactic tokens in our annotation. [should add also retweet at-mentions —YI] These statistics are obtained on 140 character-limited tweets.

Acronym abbreviations. How should we syntactically analyze acronym tokens like *idc* (abbreviating "I don't care") and *rn* ("right now")? Should they be decomposed into their component words, and if so should those words be "normalized" into explicitly spelled out intermediate forms? [this sentence should be deleted —YI] [As we already know from previous sections, *idc* is not tokenized and tagged as verb, we follow ... —YI] We follow **?** and annotate their syntax as a single word without normalization. Their syntactic functions are decided according to their context. **?** studied the necessity of normalization in social media text and argued that such normalization is problematic. Our solution to the syntax of abbreviations follows the spirit of his argument. Because abbreviations which clearly carry syntactic functions only constitute 0.06% of the tokens in our dataset, we believe that normalization is an unnecessarily complicated step.[this should be moved to tokenization section, but we can mention again here for emphasizing. —YI]

Non-syntactic tokens. The major characteristic that distinguishes tweets from standard texts is that a large proportion of tokens don't carry any syntactic function. In our annotation, there are five [six —YI] types of non-syntactic tokens: sentiment emoticons, retweet markers, topical hashtags, referential URLs, and truncated words [and retweet at-mentions —YI].[4] Figure 1 illustrates examples of these non-syntactic tokens. As discussed above, these are generally tagged with the *other* (X) part of speech, except emoticons, which are tagged as *symbol* (SYM). In our annotation, 7.5% [should change according to tab1 —YI] of all tokens are non-syntactic; detailed statistics can be found in Table 1.

It is important to note that these types may, in some contexts, have syntactic functions. For example, besides being a discourse marker, *RT* can abbreviate the verb `retweet`, and emoticons and hashtags may be used as content words within a sentence[at-mentions can be a normal vocative proper noun —YI]; see Figure 2. Therefore, the criteria for [whether —YI] annotating a token as non-syntactic must be context-dependent.

Inspired by the way UD deals with *punctuation* (which is canonically non-syntactic), we adopt the following conventions:[shall we mention how we segment sentences? Seems relevant here —YI]

- If a non-syntactic token is within a sentence that has a clear predicate, it will be attached to this predicate;
- If the whole sentence is made of a sequence of non-syntactic tokens, we attach all these tokens to the first one;
- Non-syntactic tokens are mostly labeled as *discourse*, but URLs are always labeled as *list*, following the UD_English dataset. [For retweet at-mention case, we attach the retweet at-mentions to the RT sign, so that the retweet action and the people whose tweet is being retweeted could be connected.[5] —YI]

? proposed an additional preprocessing step, *token selection*, in their annotation process. They required the annotators to first select the non-syntactic tokens and exclude them from the final dependencies annotation. In order to keep our annotation conventions in line with UD norms [and preserve the original tweets as much as possible —YI], we include non-syntactic tokens in our annotation following the conventions above. Compared with **?**, we also gave a clear[much clearer —YI] definition of non-syntactic tokens, which helped us avoid confusion during annotation.

Retweet construction. Figure 1 shows an example of the retweet construction (*RT @coldplay :*). This might be treated as a verb phrase, with *RT* as a verb and the at-mention as its object. This solution would lead to an uninformative root word and,

[4] The tweets we analyze have at most 140 characters. Although Twitter has doubled the tweet length limit to 280 characters since our analysis, we believe this type of token will still remain.

[5] We can also follow the first convention to attach the retweet at-mention to its predicate, but we think it is better for downstream tasks.

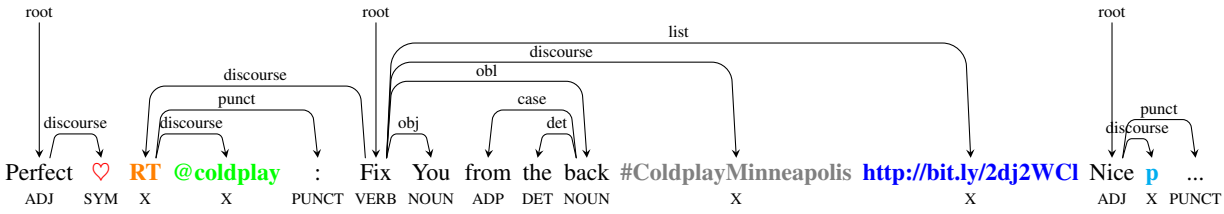

Figure 1: An example tweet that contains non-syntactic tokens: sentiment emoticon, retweet marker, retweet at-mention, topical hashtag, referential URL, and truncated word. This example tweet is a concatenation of three real tweets.

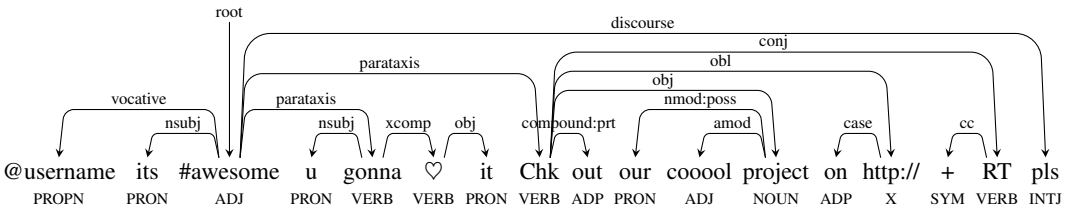

Figure 2: An example tweet with informal but syntactic tokens. This is a contrived example inspired by several tweets.

since this expression is idiomatic to Twitter, might create unnecessary confusion for downstream applications aiming to identify the main predicate(s) of a tweet. We therefore treat the whole expression as non-syntactic, including assigning the *other* (X) part of speech to both *RT* and *@coldplay*, attaching the at-mention to *RT* with the *discourse* label and the colon to *RT* with the *punct*(uation) label, and attaching *RT* to the predicate of the following sentence[since we have introduced retweet at-mentions in the non-syntactic tokens, here we can just briefly justify our choice. —YI].

Constructions handled by UD. A number of constructions that are especially common in tweets are well handled by UD conventions: ellipsis, irregular word orders, and paratactic sentences [or phrases/component —YI] not explicitly delineated by punctuation.

Vocative at-mentions. Another idiomatic construction on Twitter is an at-mention as a sign that a tweet is a reply to a tweet by the mentioned user[not necessary, can be just mentioning somebody. should be careful to say it. We can say this construction include 1. reply; 2. mention sb. Both cases are similar to general vocative proper noun case in standard texts —YI]. We treat these at-mentions as vocative expressions, labeling them as *proper noun* (PROPN)[here is confusing that PROPN could be a label in dependencies. We can say in POS sections that the decisions on some twitter specific tokens can be made only analyzing syntax together. —YI] and attaching them to the following predicate with the label *vocative* (see Figure 2 for an example) [just as UD guidelines —YI].

2.5 TWEEBANK V2

Following the guidelines presented above, we create a new annotated[del? —YI] Twitter [Twitter dependency —YI] treebank, which we call TWEEBANK V2.

2.5.1 Data Collection

TWEEBANK V2 is built on the original data of TWEEBANK V1 (840 unique tweets, 639/201 for training/test set), along with an additional 210 tweets sampled from the POS-tagged dataset of **?** and 2,500 tweets sampled from the Twitter stream from February 2016 to July 2016.[6] The latter data source consists of 147.4M English tweets after being filtered by the *lang* attribute in the tweet JSON and *langid.py* toolkit.[7]

2.5.2 Annotation Process

Our annotation process was conducted in three stages. In the first stage, 18 researchers worked on the TWEEBANK V1 proportion and created the initial annotations in one day. Before annotating,

[6] Data downloaded from https://archive.org/.
[7] https://github.com/saffsd/langid.py

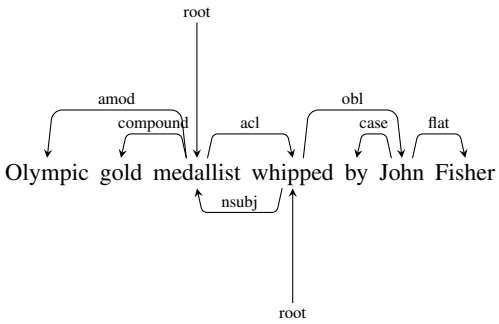

Figure 3: An example of disagreement; one annotator's parse is shown above, disagreeing arcs from the other annotator are shown below. This is a real example in our annotation.

they were given a tutorial overview of the [general —YI] UD annotation conventions and our guidelines [specifically for annotating tweets —YI]. Both the guidelines and annotations were further refined by the authors of this paper to increase the coverage of our guidelines and solve inconsistencies between different annotators during this exercise. In the second stage, a POS tagger and parser were trained on the annotated data from the first stage (1,050[changed to 1050 —YI] tweets in total), and [were? —YI]used to automatically analyze the sampled 2,500 tweets. Authors of this paper manually corrected the parsed data. Finally, an extra layer of word-level normalization[see 10 th col of conllu data, also mention we could recover the original tweets also from this col (tokenization) —YI] was manually annotated for data analysis purposes.[should mention tokenization process, say we tokenize V1 and train tokenizer for V2 data, then manually correct them. Good story :) —YI]

We report the inter-annotator agreement between the annotators in the second stage[tokenization is easier, did not do inter-annotator agreement —YI]. The agreement on POS is 96.6%, the unlabeled dependency agreement is 88.8% and the labeled dependency agreement is 84.3%. Further analysis shows the major disagreements on POS involve entity names (30.6%) [noun phrases or proper noun phrases, do we need example here? —YI] and topical hashtags (18.1%). Taking the example in Figure 1, "Fix you" [need to relate to previous error analysis, entity names maybe? —YI]can be understood as a verbal phrase but also as the name of the Coldplay's single and tagged as proper noun. [need to say the reason why dependency inter-annotator agreement is low? 1. POS disagreement lead to big difference in understanding the semantics. 2. Some special constructions like ellipsis lead to different view of tweets. Fig3 is an example of 2. —YI]An example of a disagreement on dependencies is shown in Figure 3. Depending on whether this is an example of an empty auxiliary verb, or a clause-modified noun, either annotation is plausible.

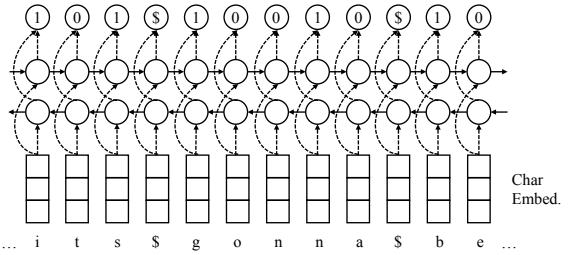

Figure 4: The bi-LSTM tokenizer model that segments 'its gonna be' into 'it s gon na be'.

3 Pipeline

We present a pipeline system to parse tweets into universal dependencies. We evaluate each component individually, and the system as a whole.

3.1 Tokenizer

Tokenization, as the initial step of many NLP tasks, is non-trivial for informal tweets, which include hashtags, at-mentions, and emoticons (**?**). Context is often required for tokenization decisions; for example, the asterisk in *4*3* is a separate token signifying multiplication, but for the asterisk in *sh*t* works as a mask to evoke censorship and should not be segmented.

We introduce a new character-level bidirectional LSTM (bi-LSTM) sequence-labeling model (**??**) for tokenization. Our model takes the raw sentence and tags each character in this sentence as whether it is the beginning of a word (1 as the beginning and 0 otherwise). Figure 4 shows our tokenization model. Space is treated as an input but consistently assigned a special tag $.

Experimental results. We trained our tokenizer on the training portion of TWEEBANK V2 combined with the UD_English training dataset and tested on the TWEEBANK V2 test set. We report F_1 scores, combining precision and recall for token identification. Table 2 shows the tokenization results, compared to other available

System	*F1*
Stanford CoreNLP	96.6
Twokenizer	94.4
UD pipe v1.2	97.3
our bi-LSTM tokenizer	**98.3**

Table 2: Tokenizer comparison on the TWEEBANK V2 test set.

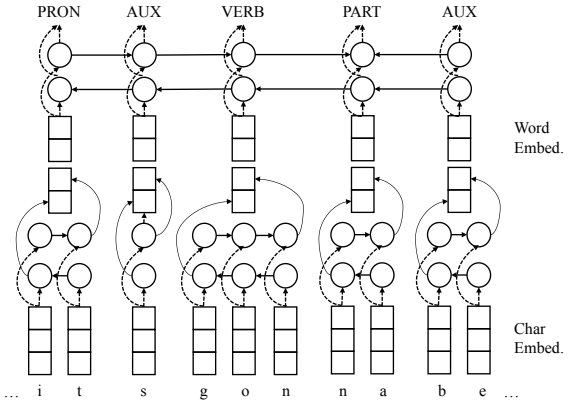

Figure 5: The bi-LSTM POS tagger model that tags 'it s gon na be' as `PRON AUX VERB PART AUX`.

tokenizers. Stanford CoreNLP (**?**) and Twokenizer (**?**) systems are rule-based systems and were not adapted to the UD tokenization scheme. The UD pipe v1.2 (**?**) model was re-trained on the same data as our system. Compared with the UD pipe, we use LSTM instead of GRU in our model and we also use a larger size of hidden units (64 against 20), which has stronger representation power. [we need to say what their model was; why does ours work better? from their paper, it seems that they used a GRU instead of an LSTM ... is that all? do we win because of better tuning, or what? —NAS][Y/L done.] Our bi-LSTM tokenizer achieves the best accuracy among all these tokenizers. These results indicate the value of statistical modeling in tokenization for informal texts.

3.2 Part-of-Speech Tagger

Part-of-speech tagging for tweets has been extensively studied (**????**). On the annotation scheme designed in §2.3, based on UD and adapted for Twitter, we compared several existing systems and also two bi-LSTM systems similar to **?** and **?**, one using word vectors and the other using word and character vectors (see Figure 5). All systems were re-trained on the combination of the UD_English and TWEEBANK V2 training sets. We use Twitter-specific glove embeddings released by **?** in all neural taggers and parsers.[8]

System	*Precision*
Stanford CoreNLP	90.4
? (greedy)	94.2
? (CRF)	**95.1**
?	91.8
our word bi-LSTM	89.2
our character + word bi-LSTMs	91.5

Table 3: POS tagger comparison on gold-standard tokens in the TWEEBANK V2 test set.

System	*F1*
Stanford CoreNLP	92.1
our bi-LSTM tokenizer (§3.1)	93.6

Table 4: **?** POS tagging performance with automatic tokenization on the TWEEBANK V2 test set.

Experimental results. We tested the POS taggers on the TWEEBANK V2 test set. Results with gold-standard tokenization are shown in Table 3. The careful feature engineering in the POS tagger of **?** outperforms our neural network models. (That tagger also makes use of **?** clusters derived from a large collection of unannotated tweets. Those clusters did not improve the performance of our bi-LSTM models.)

Results of the **?** with non-greedy inference on automatically tokenized data are shown in Table 4. We see that errors in tokenization do propagate, but tagging performance is above 93% with our tokenizer.

3.3 Parser

Social media applications typically require processing large volumes of data, making speed an important desideratum. We therefore begin with the neural greedy stack LSTM parser introduced by **?**, which can parse a sentence in linear time and harnesses character representations, which should help mitigate the challenge of spelling variation. We encourage the reader to refer their paper for more details about the model.

In our preliminary experiments, we train our parser on the combination of UD_English and

[8] http://nlp.stanford.edu/data/glove.twitter.27B.zip

System	UAS	LAS	SP
?	81.6	77.2	0.3
?	81.9	77.7	1.7
?	80.4	75.8	2.3

Distillation ($\alpha = 1.0$)	82.2	78.0	2.3
Distillation ($\alpha = 0.9$)	82.4	78.1	2.3
Distillation w/ exploration	82.5	78.4	2.3

Table 5: Dependency parser comparison on TWEEBANK V2, with automatic POS tags. The *SP* column shows the parsing speed evaluated by the number of thousand tokens the model processed per second. For fair comparison, we limit the number of CPU used in **?** experiments to 1.

TWEEBANK V2 training sets. Gold-standard tokenization and automatic POS tags are used. Automatic POS tags are assigned with 5-fold jackknifing. Hyperparameters are tuned on the TWEEBANK V2 development set. Unlabeled attachment score and labeled attachment score (including punctuation) are reported. All the experiments were ran on a Xeon E5-2670 2.6 GHz machine.

? and others have pointed out that neural network training is nondeterministic and depends on the seed for the random number generator. Our preliminary experiments confirm this finding, with a gap of 1 LAS on development data between the best (75.8) and worst (74.8) runs. To control for this effect, we report the average of five differently-seeded runs, for each of our models and the compared ones. [please check! we did this for all systems, not just ours, right? —NAS][Y/L yes. added]

Initial results. The first section of Table 5 compares the stack LSTM with TWEEBOPARSER (the system of **?**) and the state-of-the-art parser in the CoNLL 2017 evaluations, due to **?**, both of which are graph-based parsers requiring superlinear runtime. [can we quantify how much time each one takes, either in tweets parsed per second or seconds per tweet? —NAS][Y/L done.] Both of the comparison systems are re-trained on the same data as our system. Our system lags behind by nearly two LAS points but runs faster than both of them.

Ensemble. Due both to ambiguity in the training data—which most loss functions are not robust to (**?**), including the log loss we use, following **?**—and due to the instability of neural network training, we follow **?** and consider an ensemble of twenty parsers trained using different random initialization. To parse at test time, the transition probabilities of the twenty members of the ensemble are averaged. The result achieves LAS of 79.4, outperforming all three systems above (Table 5). However, ensembling 20 parsers also significantly slows down the parsing speed and leads to the slowest system in our comparison.

Distillation. The shortcoming of the 20-parser ensemble is, of course, that it requires twenty times the runtime of a single greedy parser. **?** proposed the distillation of 20 greedy transition-based parser into a single *graph-based* parser; they transformed the votes of the ensemble into a structured loss function. However, as Kuncoro et al. pointed out, it is not straightforward to use a structured loss in a *transition-based* parsing algorithm. Because fast runtime is so important for NLP on social media, we introduce a new way to distill our greedy ensemble into a single transition-based parser (the first such attempt, to our knowledge).

Our approach follows **?** and **?**. Note that training a transition-based parser typically involves the transformation of the training data into a sequence of "oracle" state-action pairs. Let $q(a \mid s)$ denote the distilled model's probability of an action a given parser state s; let $p(a \mid s)$ be the probability under the ensemble (i.e., the average of the 20 separately-trained ensemble members) [check —NAS] [Y/L checked]. To train the distilled model, we minimize the interpolation between their distillation loss and the conventional log loss:

$$\operatorname{argmin}_q \quad \alpha \sum_i \underbrace{\sum_a -p(a \mid s_i) \cdot \log q(a \mid s_i)}_{\text{distillation loss}} \tag{1}$$
$$+ \ (1-\alpha) \sum_i \underbrace{-\log q(a_i \mid s_i)}_{\text{log loss}}$$

Distilling from this parser leads to a single greedy transition-based parser with 78.1 LAS—better than past systems but worse than our more expensive ensemble. The effect of α is illustrated in Figure 6; generally paying closer attention to the ensemble, rather than the conventional log loss objective, leads to better performance.

Learning from exploration. When we set $\alpha = 1$, we eliminate the oracle from the estimation procedure (for the distilled model). This presents

Pipeline	Metrics	ours	SOTA stack
Tokenization	*F1*	98.3	96.6
POS tagging	*Precision F1*	93.7	92.1
Universal dependencies	*LAS F1*	74.1	70.3

Table 6: Evaluating our model in pipeline manner. [should this be "F1"? shouldn't the last line be LAS? —NAS][Y L added metrics column]

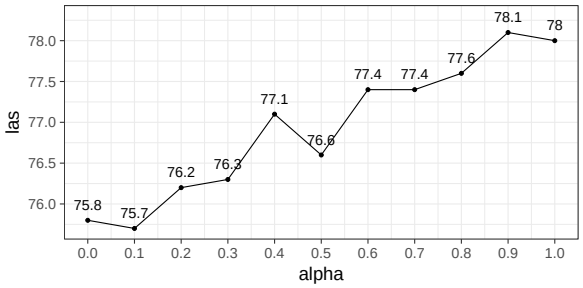

Figure 6: The effect of α on distillation.

an opportunity to learn with *exploration*, by randomly sampling transitions from the ensemble, found useful in recent methods for training greedy models that use dynamic oracles (**?**). We find that this approach outperforms the conventional distillation model, coming in only one point behind the ensemble (last line of Table 5).

Pipeline evaluation. Finally, we report our full pipeline's performance in Table 6. We also compare our model with a stack of the state-of-the-art systems (namely, the *SOTA stack*): Stanford CoreNLP tokenizer, **?**'s tagger, and **?**'s parser. Our system differs with the SOTA stack in the tokenization and parser components. From Table 6, our system outperforms the SOTA stack when evaluated in pipeline manner. The results also emphasize the importance of segmentation: without gold segmentation, UD parsing performance drops by more than four points.

4 Conclusion

We study the problem of parsing tweets into universal dependencies. We adapt the UD guidelines to cover special constructions in tweets and create the TWEEBANK V2, which has 55,607 tokens. We characterize the disagreements among our annotations and argue that inherent ambiguity in this genre makes consistent annotaiton a challenge. Using this new treebank, we build a pipeline system to parse tweets into UD. We also propose a new method to distill an ensemble of 20 greedy parsers into a single one to overcome annotation noise without sacrificing efficiency. Our parser achieves an improvement of 2.6 [which comparison are you quoting here? —NAS][Y L fixed] in LAS over a strong baseline and outperforms other state-of-the-art parsers in both accuracy and speed.
